A *Photorhabdus* Natural Product Inhibits Insect Juvenile Hormone Epoxide Hydrolase

Simple urea compounds (“phurealipids”) have been identified from the entomopathogenic bacterium *Photorhabdus luminescens*, and their biosynthesis was elucidated. Very similar analogues of these compounds have been previously developed as inhibitors of juvenile hormone epoxide hydrolase (JHEH), a key enzyme in insect development and growth. Phurealipids also inhibit JHEH, and therefore phurealipids might contribute to bacterial virulence.

Introduction

Natural products have been used in medicine since ancient times, and especially in the past 70 years they have served us well as anti-infective, anticancer and other therapeutics. [1, 2] Despite their great benefit to human health it is mostly unknown why nature has developed these compounds and what their biological roles are. [3, 4] although examples of natural products acting as virulence factors, [5] signalling molecules [6] and antimicrobials [7] are known. Entomopathogenic bacteria of the genus *Photorhabdus* live in symbiosis with nematodes of the genus *Heterorhabditis*, and together they are able to infect and kill

insect larvae. Probably because of the complex bacterial interactions with the nematode host and the insect prey (communication within the bacterial community and between bacteria and nematodes, virulence against the insect prey, defence against food competitors) these bacteria are producers of several natural products.

Here, we describe urea lipid compounds, which we name “phurealipids” (Photobacterium urea lipids) produced by the insect pathogen Photobacterium luminescens to inhibit juvenile hormone epoxide hydrolase (JHEH), a key enzyme in insect development and growth; similar compounds have been developed chemically as insecticides.

Results and Discussion

A detailed HPLC/MS analysis of P. luminescens TTO1 showed the presence of four compounds (1–4) with m/z between 215 and 257 [M+H]⁺ (Table S1 in the Supporting Information). The molecular formulae of 1, 3 and 4 as determined by HR-EI-MS (Table S1) in addition to their mass fragmentation patterns indicated either a glycine amide or a urea-derived structure; the loss of 57 Da is characteristic for either a glycine or a methyl urea moiety (Figure 1). The structure and nature of the alkyl side chains were confirmed by labelling experiments (Table S1). Briefly, 1–3 were labelled with fully deuterated leucine, thereby indicating the presence of a leucine-derived iso-branched fatty acid; no labelling was observed with deuterated valine (indicative of iso even branched amines) or propionic acid (indicative of uneven linear amines) for any compound. A linear, even-numbered side chain similar to that from standard fatty-acid biosynthesis was assumed for 4. Compounds 1, 3 and 4 showed the expected labelling with deuterated L-[(methyl-²H₃)]-methionine exclusively at the polar moiety and not the side chain (where it could also occur following the biosynthesis of methylated fatty acids), thus confirming a methyl urea moiety (Table S1). This was subsequently proven by chemical synthesis of both glycine amide and the methyl urea derivative of 4 (identical tᵢᵢ values for synthetic and natural 4). Compound 2 showed a neutral loss of 43 Da, corresponding to the desmethyl derivative of 1 (Figure 2).

Based on the structures of the identified phurealipids (Scheme 1), a biosynthetic pathway was postulated starting from different fatty-acid-derived aldehydes, which are subsequently transformed into the corresponding amines, carbamoylated and finally methylated (Scheme 2). Two carbamoyltransferases were identified in the genome of the producing strain. Gene disruption by plasmid integration (Figure S1 in the Supporting Information) into one of them, plu2076 (here renamed pliA (phurealipid)), led to complete loss of phurealipid production. Disruption of the second carbamoyltransferase, plu4565, did not affect phurealipid biosynthesis, although these mutants were no longer able to produce a virulence factor that we termed “Photobacterium clumping factor” or “PCF,” the structure of which is currently unknown. Despite the fact that more than 15 methyltransferase homologues were identified in the P. luminescens genome, comparative genome analysis between different Photobacterium and Xenor-
spread in *P. luminescens* strains (Figure 3, Figure S2) but very rare in *Photorhabdus asymbiotica* or *Photorhabdus temperata*, consistent with the fact that no plu2076 homologue could be found in the genome of *P. asymbiotica*. However, three *Xenorhabdus* strains isolated in Vietnam and related to *Xenorhabdus ehlersii* DSM 16337 showed production of 1 (Figure S3).

In independent research, closely related synthetic compounds have been previously described as inhibitors of insect juvenile hormone epoxide hydrolase (JHEH). In conjunction with juvenile hormone esterase (JHE), JHEH is a key player in the degradation of juvenile hormone (JH), which regulates both growth and development of insect larvae and reproductive functions of adults, and is also produced by the plant *Cyperius iria* as a defence mechanism against insects. Importantly, *P. luminescens* phurealipids and the related synthetic insecticides are structurally similar to JH (Scheme 2), thus suggesting a possible mode of action. We tested all phurealipids against JHEH purified from caterpillars of the tobacco hornworm *Manduca sexta* and demonstrated that 1, 3 and 4 showed IC$_{50}$ values of 6.5 ± 0.9, 50 ± 4, and 10.7 ± 1.2 μM, respectively. These are in a similar range to that observed for the known synthetic inhibitor 13 (Scheme 1, Table S2; IC$_{50}$ = 2.3 ± 0.6 μM) and is in agreement with comparable $K_I$ values (1.80 ± 0.30 and 0.35 ± 0.04 μM for 1 and 13, respectively; Figure S4). Although desmethylphurealipid B (5) showed weak activity against JHE (IC$_{50}$ = 25 ± 4 μM), no other derivatives showed activity (> 100 μM) against either JHE or JHEH (Table S2).

Upon infection of *Galleria mellonella* larvae, *P. luminescens* produced phurealipids at up to 200 μM (≈ 44 mg L$^{-1}$; Figure S5) as determined by HPLC/MS. This would be sufficient to inhibit JHEH and thus might lead to an increase in JH. JH accumulation in *Drosophila melanogaster* inhibits the production of antimicrobial peptides (AMPs), thus indicating that JH acts as a humoral immuno-suppressor. Hence, manipulation of JH levels influences not only insect development but also the efficacy of the immune response. Taken together, these data suggest that phurealipids contribute to the overall virulence of
P. luminescens by inhibiting JHEH activity and therefore limiting AMP production.

To test this hypothesis, we used quantitative reverse-transcriptase PCR to measure the RNA levels of certain AMP genes (lysozyme, gallerimycin, moricin, and cecropin) in caterpillars of M. sexta and the greater waxmoth G. mellonella challenged with Serratia entomophila or Salmonella enterica, respectively, following injection of different urea lipid compounds (Figure S6). The known synthetic inhibitor 13 demonstrated the best activity (lower levels of AMP RNAs relative to the control). Of the natural compounds, desmethylphurealipid A (2) was the most active in this assay but showed no JHEH inhibitory activity in vitro, thus suggesting other or additional JHEH-independent activities for phurealipids in vivo.

We also tested whether urea lipids predicted to lead to JH III accumulation by JHEH inhibition influence the embryonic development of the emerging insect model organism Tribolium castaneum. As methoprene was described as a JH III mimic used as insecticide, it was used as positive control for 13 (the most active urea compound inhibiting JHEH). All T. castaneum embryos treated with methoprene proceeded through gastrulation, germ band elongation and germ band retraction normally, but failed to internalise the remaining yolk sac during dorsal closure (Figure S7; Supporting Movie 1). The result was significant compared to the PBS and DMSO controls (Figure S7c), thus confirming the insecticidal effect of this compound. [19, 20] In contrast, embryos treated with 13 were able to proceed through dorsal closure normally (Figure S7, Supporting Movie 1), and the percentage of embryos successfully completing development did not differ significantly from those subjected to PBS and DMSO (Figure S7).

JH has been reported to influence gene expression in protozoan termite gut symbionts [21] and to play a role in Ca2+ homeostasis, [22] in addition to exerting epigenetic control of gene expression. [23] Based on their structural resemblances, similar activities might be exist for phurealipids. Indeed, the desmethyl urea lipids in particular exhibited very strong activity against Leishmania donovani and were in fact at least 10 times more active than the methylated derivatives (Table S2).

L. donovani, the causative agent of leishmaniasis (kala-azar), is not known to employ any JH-like regulatory pathways, but the promising activity of such simple compounds will be studied in more detail in the future. Further bioactivity tests revealed neither antibacterial nor antifungal activity for any phurealipid, and although other urea derivatives are quorum quenching compounds in Gram-negative bacteria, [24] no such activity was observed for phurealipids. In experimental infections of the caterpillar M. sexta, no difference in virulence was observed between
between the pilA insertion mutant and the parental wild-type strain. Nevertheless, because of the large redundancy of virulence factors in this bacterium it is likely that the contribution of the phurealipids to the overall virulence is masked. Precedence for this can be seen in the observation that strains lacking the highly potent Mcf1 toxin remain as virulent as the wild type, and disruption of rhabdodeptide biosynthesis in the related bacterium Xenorhabdus nematophila had only a slight effect on overall toxicity whereas the pure compounds showed insecticidal activity. Moreover, it has been proposed that the “stacking” of multiple virulence factors gives _P. luminescens_ a selective advantage during typical suboptimal infection scenarios and in diverse hosts in nature.

It is interesting that _P. luminescens_ produces a small library of phurealipids in similar amounts, as has been observed for other compound classes, such as rhabdodeptides, xentrival-peptides and taxllalids. Because the nematode vector shows little insect host specificity,[26–28] we propose that this might provide _P. luminescens_ with the ability to inhibit diverse JHEFs from a range of insect orders. JHs differing in the presence of methyl or ethyl substituents, degree of saturation and epoxide moieties have been described from different insects, thus making the presence of slightly different JHEFs quite likely.[30]

The phurealipids offer a rare example of a compound class originally developed by synthetic chemists to address a specific molecular target, but which had in fact already been “discovered” by _P. luminescens_ much earlier. We can draw parallels with the cultivation and use of antifungal-producing Streptomyces by leaf-cutting ants[31,32] or bark beetles[33] to protect their fungal gardens against pathogenic fungi, similar to humans using such compounds in antifungal therapy. These examples clearly highlight the value of organisms producing natural product, both as sources of molecules and as inspiration for much-needed novel bioactive compounds.
